G27: Does hospital length of stay have any influence on the rate of Surgical Site Infection (SSI)/Periprosthetic Joint Infection (PJI) in patients undergoing major orthopedic procedures?

Fatih Yıldız, Ahmet Durcan Yavuz, Osman Çiloğlu, Atul F. Kamath, Waleed A Al-Saadan, Ilker Uçkay, Amir Khoshbin, Walid Atef Ebeid, Wael Barsoum, Peng Xu

Response/Recommendation:

Yes. Longer hospital length of stay is associated with an increased risk of SSI/PJI. However, using the available data, the real cause behind this association could not be explained.

Strength of recommendation: Moderate

Delegate vote:

Rationale:

Surgical site infections (SSIs) and prosthetic joint infections (PJIs) are significant concerns after major orthopedic surgeries, impacting patient outcomes and healthcare costs. There are modifiable and non-modifiable risk factors for SSI/PJI, including patient- and surgeon-related factors. Although several perioperative measures, such as preoperative patient optimization, MRSA decolonization or use of prophylactic antibiotics, have been described before, the influence of hospital length of stay (LOS) on the rates of SSI/PJI, and the antibiotic resistance of the corresponding pathogens, are less reported. Several studies have investigated the relation between prolonged LOS and the risk of SSI/PJI. While some studies have identified a correlation between prolonged LOS and increased SSI risk [1–3], others have found no significant association [4, 5]. This discrepancy may be attributed to the complex interplay of factors influencing SSI development, such as patient demographics, comorbidities, type of surgical procedure, and postoperative care.

Triantafyllopoulos et al. in their retrospective study of 36,494 primary total hip arthroplasties (THA), observed an association between longer LOS and PJI, but this association was not independent of other factors such as obesity and coronary artery disease[6]. Similarly, Smucny et al. using the Nationwide Inpatient Sample (NIS) database to review 241,193 patients undergoing total shoulder arthroplasty, reported an association between increased LOS and SSI, but the causal relationship remained unclear due to potential unmeasured confounders [7]. These findings underscore the challenges in isolating the independent effect of LOS on SSI rates.

Several studies explore the influence of longer LOS on the risk of infection. Ridgeway et al. reported that the length of hospitalization before surgery was significantly associated with an increased risk of SSI after THA and hemiarthroplasty [1]. In addition, patients undergoing a hemiarthroplasty stayed in hospital for longer than patients undergoing a THA due to optimization before surgery. Another study by Omeis et al. also identified increasing LOS as a significant risk factor for SSI in patients undergoing spinal tumor surgery [2]. To find a cutoff value, Song et al. reported that a preoperative hospital stay of more than three days was a risk factor for SSI after THA and total knee arthroplasty (TKA) [3].

Contrary to most studies reporting the relation between longer LOS and increased risk of SSI/PJI, enhanced recovery programs (ERP) or day-surgeries have not shown this relation.

Yuan et al. in their retrospective analysis of a prospectively established database of patients undergoing posterior thoracolumbar fusion for degenerative spinal deformity, found that an ERP successfully reduced postoperative LOS without increasing SSI rates [8]. Similarly, Mundi et al. using the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) database to evaluate 330,000 patients, reported that same-day discharge and accelerated discharge (1-day LOS) after total joint arthroplasty did not increase the risk of SSI [9]. Therefore, rapid recovery is not considered as a concern for infection, and the surgeons who routinely do rapid recovery or outpatient joint replacement surgery favor early discharge to reduce the risk of SSI/PJI.

The relationship between prolonged LOS and SSI rates has been reported in various studies focusing on specific patient populations and surgical procedures [10]. Although most of the studies investigate this relation in joint replacement and spine surgeries, the risk of SSI was shown to be higher in trauma and pediatric orthopedic surgeries when the LOS was prolonged, as well [11–14].

We conducted a systematic review and meta-analysis of the available literature to answer this question. PubMed/Medline, Scopus and Embase databases were searched, from inception to September 2024 to identify all the studies investigating the association between LOS and SSI/PJI in patients undergoing major orthopedic procedures. This meta-analysis included eighteen studies, comprising a variety of designs: six prospective cohort study, one prospective two-subcohort studies, one retrospective two-subcohort studies, seven retrospective case-control studies, and three retrospective database cohort studies utilizing databases, all examining the association between LOS and the rate of SSI/PJI in patients undergoing major orthopedic procedures. [7, 12, 15–29]. Studies with participants who have prolonged LOS because of infection were excluded. Figure 1 compares the mean values of different parameters in patients with and without SSI/PJI. Heterogeneity was found to be moderate-high in subgroups and overall ($I^2 = 97\%^{\text{trauma}}$, $98\%^{\text{arthroplasty}}$, $58\%^{\text{spine}}$, $100\%^{\text{general}}$ orthopedics, 100% total). The combined mean difference of the studies was calculated as 7.78 days (95% CI: 3.75-11.80). These results showed statistically significantly longer LOS in SSI groups. In the specific subgroup of general orthopedics, there was no statistically significant difference in the mean LOS, between the groups with and without SSI. It was also not affected by age, BMI, gender (p=0.5725). Using the available data, neither determining a cutoff value for the LOS nor identifying rates of SSI/PJI for different LOS intervals were possible. More importantly, included studies did not explain why longer LOS was associated with the increase in infection risks.

Prolonged hospital stay before orthopedic surgery is a potential risk for acquisition of antibiotic-resistant microorganisms. In implant-related orthopedic surgery, including for arthroplasty, there are fewer articles. In terms of antibiotic resistance of future SSI pathogens, Davat et al retrospectively investigated if the methicillin-resistance of SSI due to staphylococci (the hallmark of orthopedic SSI) in association to the LOS immediately before the index surgery, and found no more resistance [30] and necessity to broaden the spectrum of perioperative antibiotic prophylaxis during surgery after a long hospitalization period.

In conclusion, the present systematic review and meta-analysis demonstrated a statistically significant relationship between LOS and the risk of subsequent SSI/PPJI, indicating that prolonged LOS is associated with an increased risk of SSI/PJI after major orthopedic surgeries, whereas the association with more resistant SSI pathogens remains less clear. This finding underscores the importance of optimizing LOS in orthopedic surgery to minimize SSI/PJI risk and improve patient outcomes. However, with the available data, we cannot explain completely why an increased LOS would influence the rate of infection. Probably, the

reason is multifactorial and maybe associated with other risk factors in longer LOS such as patients' immune suppression, revision surgery or the ASA-Score.
